### **Background:**

Large numbers of people suffer from long-term sequelae that continue after COVID-19 infection. It has been shown that intermittent hypoxia-hyperoxia therapy (IHHT) may promote improvements in physical and cognitive performance. The aim of the study was to investigate the effects of complementary IHHT to a multidisciplinary post-COVID rehabilitation.

### **Methods:**

In a prospective, controlled trial 150 consecutive patients with post-COVID-19 condition were assigned to two groups: intervention group (IG, n=68) and control group (CG, n=82). Both groups completed multimodal rehabilitation. Only the IG additionally received a regular IHHT).

### **Results:**

Patients receiving IHHT were younger than patients of the control group ( $51.1 \pm 11.5$  vs.  $59.5 \pm 10.4$  years,  $p < 0.001$ ). Furthermore, systolic blood pressure was lower in the IG ( $129.0 \pm 15.1$ ) compared to the CG ( $138.5 \pm 16.8$  mmHg),  $p < 0.001$  at baseline. Heart rate and parameters of lung function at baseline were comparable.

In both groups the 6MWD increased significantly during rehabilitation: In the IG from 357.4m to 441m ( $p < 0.001$ ) and in the CG from 355.2m to 399.8m ( $p < 0.001$ ). The change in 6MWD was significantly higher in the IG group ( $83.6 \pm 45.8$ m) than in the CG ( $44.6 \pm 75.2$ m),  $p < 0.001$ . IHHT was well-tolerated by all subjects.

### **Conclusion:**

A complementary IHHT seems to additionally improve exercise performance in patients with post-COVID-19 condition.
